

- The instructions are the same as in Homework-0, 1.

There are 6 questions for a total of 100 points.

- (12 points) Given a strongly connected directed graph,  $G = (V, E)$  with positive edge weights along with a particular node  $v \in V$ . You wish to pre-process the graph so that queries of the form “what is the length of the shortest path from  $s$  to  $t$  that goes through  $v$ ” can be answered in constant time for any pair of distinct vertices  $s$  and  $t$ . The pre-processing should take the same asymptotic run-time as Dijkstra’s algorithm. Analyse the runtime and provide a proof of correctness.
- Counterexamples are effective in ruling out certain algorithmic ideas. In this problem, we will see a few such cases.

- (5 points) Recall the following event scheduling problem discussed in class (lecture 15):

You have a conference to plan with  $n$  events and you have an unlimited supply of rooms. Design an algorithm to assign events to rooms in such a way as to minimize the number of rooms.

The following algorithm was suggested during class discussion.

```

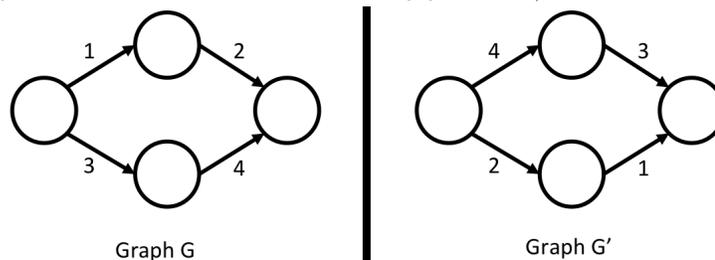

ReduceToSingleRoom( $E_1, \dots, E_n$ )
-  $U \leftarrow \{E_1, \dots, E_n\}; i \leftarrow 1$ 
- While  $U$  is not empty:
  - Use Earliest Finish Time greedy algorithm on events in set  $U$ 
    to schedule a subset  $T \subseteq U$  of events in room  $i$ 
  -  $i \leftarrow i + 1; U \leftarrow U \setminus T$ 

```

Show that the above algorithm does not always return an optimal solution.

- (5 points) A longest simple path from a node  $s$  to  $t$  in a weighted, directed graph is a simple path from  $s$  to  $t$  such that the sum of weights of edges in the path is maximised. Here is an idea for finding a longest path from a given node  $s$  to  $t$  in any weighted, directed graph  $G = (V, E)$ :

Let the weight of the edge  $e \in E$  be denoted by  $w(e)$  and let  $w_{max}$  be the weight of the maximum weight edge in  $G$ . Let  $G'$  be a graph that has the same vertices and edges as  $G$  but for every edge  $e \in E$ , the weight of the edge is  $(w_{max} + 1 - w(e))$ . (For example, consider the graph  $G$  below and its corresponding graph  $G'$ .)

Run Dijkstra’s algorithm on  $G'$  with starting vertex  $s$  and return the shortest path from  $s$  to  $t$ .

Show that the above algorithm does not necessarily output the longest simple path.

- (c) (5 points) Recall that a *Spanning Tree* of a given connected, weighted, undirected graph  $G = (V, E)$  is a graph  $G' = (V, E')$  with  $E' \subseteq E$  such that  $G'$  is a tree. The cost of a spanning tree is defined to be the sum of weight of its edges. A *Minimum Spanning Tree (MST)* of a given connected, weighted, undirected graph is a spanning tree with minimum cost. The following idea was suggested for finding an MST for a given graph in the class.

Dijkstra's algorithm gives a shortest path tree rooted at a starting node  $s$ . Note that a shortest path tree is also a spanning tree. So, simply use Dijkstra's algorithm and return the shortest path tree.

Show that the above algorithm does not necessarily output a MST. In other words, a shortest path tree may not necessarily be a MST. (*For this question, you may consider only graphs with positive edge weights.*)

3. (*Example for "greedy stays ahead"*) Suppose you are placing sensors on a one-dimensional road. You have identified  $n$  possible locations for sensors, at distances  $d_1 \leq d_2 \leq \dots \leq d_n$  from the start of the road, with  $0 \leq d_1 \leq M$  and  $d_{i+1} - d_i \leq M$ . You must place a sensor within  $M$  of the start of the road, and place each sensor after that within  $M$  of the previous one. The last sensor must be within  $M$  of  $d_n$ . Given that, you want to minimize the number of sensors used. The following greedy algorithm, which places each sensor as far as possible from the previous one, will return a list  $d_{i_1} \leq d_{i_2} \leq \dots \leq d_{i_k}$  of locations where sensors can be placed.

```

GreedySensorMin( $d_1 \dots d_n, M$ )
- Initialize an empty list
- Initialize  $I = 1, PreviousSensor = 0$ .
- While ( $I < n$ ):
  - While ( $I < n$  and  $d_{I+1} \leq PreviousSensor + M$ )  $I++$ 
  - If ( $I < n$ ) Append  $d_I$  to list;  $PreviousSensor = d_I; I++$ .
- if list is empty, append  $d_n$  to list
- return(list)

```

In using the "greedy stays ahead" proof technique to show that this is optimal, we would compare the greedy solution  $d_{g_1}, \dots, d_{g_k}$  to another solution,  $d_{j_1}, \dots, d_{j_{k'}}$ . We will show that the greedy solution "stays ahead" of the other solution at each step in the following sense:

Claim: For all  $t \geq 1, g_t \geq j_t$ .

- (a) (5 points) Prove the above claim using induction on the step  $t$ . Show base case and induction step.
- (b) (3 points) Use the claim to argue that  $k' \geq k$ . (Note that this completes the proof of optimality of the greedy algorithm since it shows that greedy algorithm places at most as many sensors as any other solution.)
- (c) (2 points) In big-O notation, how much time does the algorithm as written take? Write a brief explanation.
4. (*Example for "modify the solution"*) You have  $n$  cell phone customers who live along a straight highway, at distances  $D[1] < D[2] < \dots < D[n]$  from the starting point. You need to have a cell tower within  $\Delta$  distance of each customer, and want to minimize the number of cell towers.

(*For example, consider  $\Delta = 3$  and there are 3 customers (i.e.,  $n = 3$ ) with  $D[1] = 3, D[2] = 7, D[3] = 10$ . In this case, you can set up two cell towers, one at 6 and one at 10.*)

Here is a greedy strategy for this problem.

**Greedy strategy:** Set up a tower at distance  $d$  which is at the farthest edge of the connectivity range for the customer who is closest to the starting point. That is,  $d = \Delta + D[1]$ . Note that all customers who are within  $\Delta$  distance of this tower at  $d$ , are covered by this tower. Then recursively set up towers for the remaining customers (who are not covered by the first tower).

We will show that the above greedy strategy gives an optimal solution using modify-the-solution. For this, we will first need to prove the following exchange lemma.

*Exchange Lemma:* Let  $G$  denote the greedy solution and let  $g_1$  be the location of the first cell phone tower set up by the greedy algorithm. Let  $OS$  denote any solution that does not have cell phone tower at  $g_1$ . Then there exists a solution  $OS'$  that has a cell phone tower set up at  $g_1$  and  $OS'$  has the same number of towers as  $OS$ .

*Proof.* Let  $OS = \{o_1, \dots, o_k\}$ . That is, the locations of the cell phone towers as per solution  $OS$  is  $o_1 < o_2 < \dots < o_k$ . We ask you to complete the proof of the exchange lemma below.

- (a) (1 point) Define  $OS'$ .
- (b) (2 points)  $OS'$  is a valid solution because ... (*justify why  $OS'$  provides coverage to all customers.*)
- (c) (2 points) The number of cell phone towers in  $OS'$  is at most the number of cell phone towers in  $OS$  because... (*justify*)

We will now use the above exchange lemma to argue that the greedy algorithm outputs an optimal solution for any input instance. We will show this using mathematical induction on the input size (i.e., number of customers). The base case for the argument is trivial since for  $n = 1$ , the greedy algorithm opens a single tower which is indeed optimal.

- (a) (3 points) Show the inductive step of the argument.

Having proved the correctness, we now need to give an efficient implementation of the greedy strategy and give time analysis.

- (a) (5 points) Give an efficient algorithm implementing the above strategy, and give a time analysis for your algorithm.

5. (25 points) You are a conference organiser and you are asked to organise a conference for a company. The capacity of the conference room is limited and hence you would want to minimise the number of people invited to the conference. To make the conference useful for the entire company, you need to make sure that if an employee is not invited, then every employee who is an immediate subordinate of this employee gets the invitation (*if an employee is invited, then you may or may not invite a subordinate*). The company has a typical hierarchical tree structure, where every employee except the CEO has exactly one immediate boss.

Design an algorithm for this problem. You are given as input an integer array  $B[1..n]$ , where  $B[i]$  is the immediate boss of the  $i^{\text{th}}$  employee of the company. The CEO is employee number 1 and  $B[1] = 1$ . The output of your algorithm is a subset  $S \subseteq \{1, \dots, n\}$  of invited employees. Give running time analysis and proof of correctness.

6. (25 points) A town has  $n$  residents labelled  $1, \dots, n$ . In the midst of a virus outbreak, the town authorities realise that hand sanitiser has become an essential commodity. They know that every resident in this town requires at least  $T$  integer units of hand sanitiser. However, at least  $\lceil \frac{n}{2} \rceil$  residents do not have enough sanitiser. On the other hand, there may be residents who may have at least  $T$  units. With very few new supplies coming in for the next few weeks they want to implement some kind of sharing strategy. At the same time, they do not want too many people to get in close proximity to implement sharing. So, they come up with the following idea:

Try to *pair up* residents (based on the amount of sanitiser they possess) such that:

1. A resident is either unpaired or paired with exactly one other resident.
2. Residents in a pair together should possess at least  $2T$  units of sanitiser.
3. The number of unpaired residents with less than  $T$  units of sanitizer is minimised.

Once such a pairing is obtained, the unpaired residents with less than  $T$  units of sanitiser can be managed separately. The town authorities have conducted a survey and they know the amount of sanitiser every resident possesses. You are asked to design an algorithm for this problem. You are given as input integer  $n$ , integer  $T$ , and integer array  $P[1..n]$  where  $P[i]$  is the number of units of sanitiser that resident  $i$  possesses. You may assume that  $0 \leq P[1] \leq P[2] \leq \dots \leq P[n]$ . Your algorithm should output a pairing as a list of tuples  $(i_1, j_1), (i_2, j_2), \dots, (i_k, j_k)$  of maximum size such that (i) For all  $t = 1, \dots, k$ ,  $P[i_t] + P[j_t] \geq 2T$  and (ii)  $i_1, \dots, i_k, j_1, \dots, j_k$  are distinct. Give proof of correctness of your algorithm and discuss running time.
